چکیده: مجموعه کانی‌ها، پافت‌های واکنشی و ترکیب کانی‌های سنگهای رسی دگرگون شده منطقه جنوبغرب ماهنشان واقع در شمالغرب ایران به منظور پاسبانی تاریخچه واکنش‌های دگرگونی، مورد بررسی قرار گرفته است. تاریخچه واکنش‌ها در سنگهای رسی دگرگون شده بدون کلریتونید و کلریتونیددار کمپلکس ماهنشان جهت مطالعه روابط فازی با استفاده از نمودارهای فازی AFM, AFMn روایت فازی است. بر اساس ترکیب واقعی و ایزوگراد کانی‌ها بررسی شده است. کانی‌های اصلی در سنگهای رسی دگرگونی شده گراتیسی بدون کلریتونید در بلند پرچین عبارتند از: کارلت، استارولیت، نیترولیت، کلریتونید و کوارتز. در این سنگ‌ها ایزوگرادها جز سری دگرگونی باروین‌هستند. سنگهای رسی دگرگون شده کلریتونیددار منطقه دارای کانی‌های گراتین، استارولیت، کلریتونید، مسکوت و کوارتز هستند. در این سنگ‌ها ایزوگرادها شبیه سری دگرگونی باروین‌هستند با این تفاوت که در SENگهای بدون کلریتونید و AFMn کانی کلریتونید در ترکیب سنگهای با آلومینیم بالا را نشان می‌دهد. روابط فازی در نمودارهای AFMn و AFM برای شناخت واکنش‌های دگرگونی و ایزوگراد کانی‌ها در هر دو دسته سنگهای کلریتونیددار و بدون کلریتونید مورد استفاده قرار گرفته‌اند.

واژه‌های کلیدی: کمپلکس ماهنشان، سنگهای رسی دگرگون شده، کلریتونید، روابط فازی، تاریخچه واکنش‌ها، سری باروین.
Phase relations and reaction histories of chloritoid-free and chloritoid-bearing metapelites from the Mahneshan area, NW Iran

Abstract: Mineral assemblages, reaction textures and mineral composition of the metapelitic rocks from the Mahneshan area in NW Iran are studied to reconstruct the reaction history of the rocks. The phase relation on the real mineral chemistry AFM, AFMn compatibility diagrams and mineral isograds in chloritoid-free and chloritoid-bearing metapelites of Mahneshan Complex were studied in order to determine the reaction history. The main minerals in the graphitic metapelites (chloritoid-free schist) of the Bolandparchin are garnet, staurolite, andalusite, kyanite, fibrolite, biotite, muscovite and quartz. The isograds are typical Barrovian. Chloritoid-bearing metapelites of the area contain the minerals garnet, staurolite, chlorite, muscovite, chloritoid and quartz. The isograds are not compatible with Barrovian type, but reflect the first appearance of chloritoid in the aluminous bulk compositions. Phase relations on the AFM and AFMn compatibility diagram are used to find the metamorphic reactions in both chloritoid-bearing and chloritoid-free rocks.

Keywords: Mahneshan Complex, metapelites, chloritoid, phase relation, reactions history, Barrovian type.

1- Introduction
The chemical system K₂O-FeO-MgO-Al₂O₃-SiO₂-H₂O (KFMASH) was used to study the compatibility of the coexisting phases in the Mahneshan metapelites [1]). In this paper, we assume an equilibrium or at least a close to equilibrium condition for crystallization of different metamorphic minerals in the metapelitic rocks of the Mahneshan area.

The observed mineral assemblages, the analysis of reaction textures and the mineral compositions are used to reconstruct the reaction history of the rocks in the Mahneshan Complex. Based on field and petrography studies, four metamorphic phases have affected the area. The first phase (M₁) has been a regional metamorphic event, crystallizing garnet, biotite and muscovite. Inclusion trails within andalusite, staurolite and garnet are developed, which help to determine the relative chronology of the metamorphic and deformational phases. The second phase (M₂) has formed new minerals such as kyanite, fibrolite, staurolite, andalusite and garnet. The third phase (M₃) is contact metamorphism around younger igneous intrusions, which has produced post deformational andalusite and garnet. The last metamorphic phase (M₄) is retrograde and post-magmatic, which has affected M₁, M₃ and M₄ metamorphic assemblages, overprinting schistosities (both S₁ and S₂) of the rocks.

2- Geological setting
The area chosen for this study is located in NW of Mahneshan town in Zanjan province of Iran. The area is limited to geographical Latitudes of 36° 30’ to 37° 00’N and Longitudes of 47° 07’ to 47° 45’E (Fig.1). The Mahneshan Complex is located within the Alpine-Himalayan orogenic system of western Asia [2], [3]. Probably, the main geological
features of the area are formed during Pan African orogeny similar to central Iranian block (e.g. [4]).

In the northern part of the Takab quadrangle (Mahneshan Complex is the central part of the Takab quadrangle), a sedimentary sequence (more than 1300 m in thickness) is exposed and ranging in ages from Precambrian, Cretaceous, Eocene, Oligocene-Miocene to post-Miocene [5]. Emplacement of Precambrian and Palaeozoic rocks under the sedimentary and volcanic rocks with Oligo-Miocene age is brought up an old horst (Gor Gor, Belghes and Ghebleh Dagh horst). This horst with a trend of NW-SE extends from N to S of the area (Fig. 2). The western border of this horst is a reverse fault (Gainarjah-Chartag fault) with depression of Shirmard and Eastern border is Pari basin. The base complex is formed of Precambrian rocks which are exposed in the central part of the Mahneshan area.

3- Petrography and deformation

3.1. Structural relations and petrofabric features of pelitic rocks of the study area

Microstructure and petrographic features and field relations show that the formation of Mahneshan metamorphic complex is poly-metamorphic with four metamorphic phases (M₁, M₂, M₃ and M₄) and at least two deformational phases (D₁ and D₂). A poly-phase deformation can be considered based on two foliations, (S₁ and S₂) as well as by inclusion trails in porphyroblasts. D₁ (first deformational phase) is affected by D₂ (second and main deformational phase) with respect to the microscopic thin sections and field evidence. D₂ is the most obvious and pervasive deformation in the area while D₁ can be seen in some thin section, only.

Fig.1. Simplified structural map of Iran (compiled from [3]; [2]). MKDF = Main Kopeh-Dagh Fault, ZTZ = Zagros Thrust Zone.
3.2. Formation of foliations (S1 and S2)
The slaty cleavage S₁ (formed during the first deformation D₁) is best seen in samples from the Almalu schist where it is brought about by two mica (Bt, Ms) crystallized parallel to the slaty cleavage (Fig. 4c, 5b) and also in crenulation cleavage (Fig 5c). S₂ (formed during the second deformation D₂) is parallel to axial planes of micro-folds in intercalated quartz – feldspar rich and phyllosilicate-rich layers. This foliation represents the main regional foliation and can be recognized at all part of the metamorphic zone. S₂ foliation might have developed simultaneously with first generation of the folds and thrusts, superimposed on older structures.

3.3. Relation between deformation and metamorphism (Poly-metamorphism)
a) M₁ metamorphism
The M₁ metamorphic phase formed during D₁ deformational phase is represented by fine to medium – grained (0.5-1mm) metamorphic minerals which are present in the weakly-deformed domains. The main minerals of this metamorphic phase (with respect to inclusion in porphyroblast) are garnet, white mica, biotite, chlorite, quartz and albite.
The mica flakes may have grown as crystals parallel to bedding due to diagenetic foliation under low-grade metamorphic condition, simultaneously to the D1 deformation.

**b) M2 metamorphism**

The M2 metamorphic phase is characterized by a strong crenulation cleavage and preferred alignment of mainly mica minerals (S2) and development of new porphyroblasts including Grt, Bt, Ctd, And, Ky, Sill and St. This phase was the major regional metamorphic phase in the studied area and affected the M1 metamorphic phase. Name abbreviations are after [6].

Two main mineral assemblages formed during M2 in the graphitic schists (Bolandparcin sub area Fig.4) and non-graphitic schist (Poshtuk sub area Fig.5).

The graphitic schists assemblages (chloritoid-free) are (in addition to muscovite, quartz as KFMASH system minerals):  

\[
\begin{align*}
\text{Chl} + \text{Bt} & \quad (1) \\
\text{Bt} + \text{Grt} & \quad (2) \\
\text{Bt} + \text{Grt} + \text{And} + \text{St} & \quad (3) \\
\text{Bt} + \text{Grt} + \text{And} + \text{Ky} & \quad (4) \\
\text{Bt} + \text{Grt} + \text{Sill} & \quad (5)
\end{align*}
\]

The mineral assemblages in the non-graphitic schists are  

\[
\begin{align*}
\text{Grt} + \text{St} + \text{Chl} & \quad (6) \\
\text{Ctd} + \text{Grt} + \text{St} + \text{Chl} & \quad (7)
\end{align*}
\]

The crystallization of these minerals was found to be temporally related to the S2 fabric and D2 phase in all domains.

**c) M3 metamorphism**

The M3 metamorphic stage represents a contact metamorphic phase. This metamorphism is affected M1 and M2 regional metamorphic phases. Some minerals such as biotite and garnet are replaced the old regional metamorphic garnet due to contact metamorphism. Also and is formed in phyllosilicate-rich layers, over printing both S1 and S2 (Fig.4h). The main assemblage of contact metamorphic phase is Grt + Bt + And + Crd + Ms.

**d) M4 metamorphism**

This metamorphism is retrograde and a post-magmatic event. M4 metamorphism has affected M1, M2 and M3 metamorphic assemblages, overprinting both S1 and S2 schistosities (Fig.4b).

The mineral assemblage that formed during metamorphism (M4), is Chl + Ms. Retrograde reaction textures such as Chl after Bt and Grt are observed mainly in the regional Grt zone and St – And zone.

**3.4. Metamorphic mineral growth**

**a) Chlorite**

Primary chlorite is crystallized in the non-graphitic schists. The rocks containing primary chlorite are composed of fine-grained muscovite, chlorite, quartz and porphyroblasts of helicitic garnet and staurolite (Fig.5g). Chlorite and muscovite up to 0.3 mm long have developed in the rocks. Retrograde chlorite is crystallised after both M1 and M2 metamorphism (Fig.4b).

**b) Biotite**

Pelitic rocks from the Alemlu area (Fig.3) are phylilies or fine grained schists with lepidoblastic texture and are characterized by a slaty cleavage, which is affected by later crenulation cleavage. The mineral assemblage of these rocks is Chl + Ms + Bt + Qtz + Pl with opaque accessory minerals (Fig.4c).

**c) Garnet**

Garnet in the graphitic schists (1 up to 4 mm in diameter) usually forms idiomorphic to sub-idiomorphic, sometimes inclusion-rich grains with Bt and/or Qtz inclusion. Texture of these schists is lepidoporphyroblastic. Grt, Bt and Ms are syn-tectonic (D2), because porphyroblasts of Ms and Bt lie parallel to S2 and wrap garnet (Fig.4f). Garnet preduces D2 deformatinal phase in some sample (Fig.4e).

Most of the garnet crystals (in non-graphitic schists of Poshtuk) show spiral shape inclusion fabrics, which have traditionally been interpreted as developed during syn-tectonic (S2) growth of rotating porphyroblasts (Fig5d). Porphyroblasts of garnet up to 1.3 mm long have developed in the non-graphitic schists of the Poshtuk area (Fig.5a).

**d) Andalusite**

Andalusite exists in the chloritoid-free schists. With respect to the petrography studies, two types of andalusite can be distinguished in graphitic schists:  

The first generation of andalusite (And1) which is formed pre-tectonically to syn-tectonically (D2) in term of deformation in the crystals, pressure shadow and boudins (Fig.4e). Mica parallel to S2
wraps the andalusite. And₁ is formed during the M₂ metamorphic phase. Some of these andalusites have preserved garnet, graphite and staurolite as inclusion and show zoning under the microscope. The second generation of andalusite (And₂) is formed post-tectonically (M₃) and due to M₃ contact metamorphism. And₂ grows statically over pre-existing microfolds of S₂ foliations and phyllosilicate–rich layers (Fig.4h).

Two textural generations of biotite and garnet can be distinguished.

Mineral growth outlasted the deformation, as indicated by And₂, Grt₂ and Bt₂, porphyroblasts either growing statically over pre-existing microfolds of S₂ or replacing a former mineral that formed during regional metamorphism such as Grt₁.

e) Staurolite
Staurolite is crystallized in both chloritoid-free and chloritoid-bearing schists. There is no pressure shadow around this mineral. It seems that the staurolites are syn-D₂ (Fig.4h). S₂ schistosity wraps some staurolites. Staurolite usually forms idioblastic to sub-idioblastic, inclusion-free grains. Staurolite in chloritoid-bearing schists of Poshtuk often nucleated at the margin of garnet or in phyllosilicate–rich layers (Fig.5.e). Most of the garnet has already broken down in these rocks and staurolite is formed at the rim of garnet (Fig.5.f).

f) Chloritoid
Chloritoid was found in non-graphitic schists in the study area. It occurs in fine-grained rock matrix as lath-shaped crystals with bluish colour under the microscope (Fig.5g). These rocks consist of garnet (up to 1.3 mm) chloritoid, staurolite (up to 0.5 mm), chlorite and muscovite. Chloritoid, chlorite and muscovite are formed parallel to S₂ in non-graphitic schist that wraps spiral garnet. These minerals are syn-D₂. Therefore main mineral assemblage in these rocks, which are formed syn-M₂, is: Ctd + Grt + St + Ms + Chl + Qtz.

Fig.3. Geological map of the Mahnesan Complex whit sample locations [25].
Fig. 4. a- Sillimanite grows at the expense of biotite. b- Retrograde chlorite overprinting both S1 and S2 foliation. c- A schistosity (S1) is defined by a preferred orientation of muscovite, and biotite affected by a crenulation schistosity with an axial plane cleavage (S2) defined by Bt and Ms. d- Kayanite porphyroblast formed during M2 regional metamorphism. e- Syn-tectonically andalusite (And1) and deformed porphyroblast formed during M2 main regional metamorphism and deformed S2 foliation with rotated andalusite porphyroblast. f- Syn-tectonic garnet porphyroblasts formed during M2 metamorphism. g- Staurolite is formed syn-tectonically in the chloritoid-free schists. h- Undeformed andalusite (And2) porphyroblast has overgrown D2 micro fold during M3 contact metamorphism.
Fig. 5. a. garnet porphyroblasts (Grt) with 0.5 to 1.5 cm diameter formed in chloritoid schists. b. folding of the S1 foliation leading to the development of a S2 foliation parallel to the axial plane. c. A schistosity ($S_1$) is defined by a preferred orientation of muscovite, chloritoid and chlorite which is crenulated. d. Syn-tectonic helicitic garnet porphyroblasts(Grt) formed during M$_2$ metamorphism and garnet (Grt2) is formed during contact metamorphic phase. e. Staurolite and muscovite nucleated at the margin of garnet. f. garnet (pseudomorph) is replaced by staurolite (prograde metamorphism). g. Chlorite and chloritoid in textural equilibrium. h. staurolite pseudomorphed by muscovite
4. Mineral chemistry of peak metamorphism

In order to identify the mineral composition of major phases of metapelites in the studied samples, minerals in five representative thin sections of the rocks were analysed with the electron microprobe in GeoForschungsZentrum (GFZ) Potsdam, Germany, using a Cameca SX100 microprobe in the wavelength-dispersive mode with 15 kV acceleration Voltage, 3 nA beam current and 40 second acquisition time per analyses. The detection limit of the machine is approximately 0.1 wt%. The relative analytical errors are approximately 1%.

Sample locations are shown in Figure 3. Representative mineral analyses are provided in Tables 1, 2, and 3.

a) Chlorite
Representative analyses of chlorite are shown in Table 1. The number of cations is calculated on the basis of 28 Oxygens. Prograde chlorite is only present in non-graphitic schists. Retrograde chlorite, formed as alteration product of biotite and garnet has almost the same composition as the prograde ones. The oxide totals are between 86.87 and 89.49. The amount of Ti is between 0.01 and 0.07 atom per formula unit (apfu). The chlorites are Mn-free. Na varies from 0.00 to 0.02 apfu, and K from 0.00 to 0.03 apfu. Substitution of Al$^{3+}$ for Si$^{4+}$ is calculated using stoichiometric approach. Figure 6a after [7] shows the classification of the studied chlorites. According to this figure, chlorites are of epidote to daphnite type. This figure also shows the Fe-rich nature of the chlorites. According to Fig. 6b [8] retrograde chlorites plot on the Medium-/Low-pressure field and prograde chlorite plot close to this field.

b) Muscovite
Muscovite analyses are listed in Table 1. The number of cations is calculated on the basis of 11 oxygens. All samples of pelitic composition contain primary muscovite. There is no compositional difference between those lying parallel to the schistosity and those oblique to the S$_2$ foliation. According to Figure 6c [9], muscovite is rich in the muscovite end-member Figure 6d, paragonite being the second dominant component. The mole fractions of other components are negligible. Reduction in the phengite component of muscovite with metamorphic grade has been described by several authors (e.g. [10]; [11]; [12]) in different low-to medium pressure metamorphic terranes.

c) Biotite
Microprobe analyses of biotite are provided in Table 2. The number of cations is calculated on the basis of 11 oxygens. The amount of Ti is between 0.08 and 0.14 (apfu). Phlogopite-annite are the dominant constituents in the biotite (Fig.6d1). Ti versus Fe/(Fe+Mg) diagram for biotites from different metamorphic zones, is given in Figure 6e. Compositional ranges of biotite from various metamorphic zones in New England are from [13].
According to this figure, biotites in the studied samples plot in the Ky-St and Sil-St zones. This is in accordance with petrographical observation.

d) Garnet
Garnet compositions are listed in Table 2. In general, garnets are Fe-rich with almandine content varying between 80 and 90%. Ti is not presented or occurs in very low amounts. Figure 6g shows the chemical composition of the analysed garnets on the Alm, Pyp and (Grs+Sps) triangular diagram. Fe$^{3+}$ content of garnet were calculated based on eight cations and 12 Oxegens. Zoning profiles are from rim to rim through the core of the garnets (Fig 6k). There is significant normal zoning in the garnet from sample 43b1.

Fig. 6. d1. Plot of Ti (per 11 oxygens) as a function of Fe/(Fe+Mg) for biotite from different metamorphic zones.

e. Unshaded fields: compositional ranges of biotite from metapelites of Mahnesan ([13]). f. Composition of the studied chloritoids plotted on the Mn, Fe$^{2+}$, Mg and Fe$^{2+}$ + Mn, Al$^{3+}$, Mg triangular diagrams. Chloritoids are Fe-clinobiotite. g. Composition of the studied garnet plotted on the Fe$^{2+}$, Mg and Ca, triangular diagrams. h. Composition of the studied staurolite plotted on the Fe$^{2+}$, Mg and Mn + Ca triangular diagrams. i. Composition of the Mahnesan igneous feldspars, plotted on the An-Ab-Or diagram.
e) Chloritoid
Chloritoid is found only in Non-graphitic schists. Representative mineral compositions of chloritoids in the studied samples are given in Table 3. The number of cations is calculated on the basis of 12 Oxygens. Chloritoids are iron rich, and the Fe/Mg ratio is much higher than in the coexisting chlorite. Fig.6f, illustrates the composition of chloritoids on the Al+Fe$^{3+}$, Fe$^{2+}$+Mn, Mg and Fe$^{2+}$, Mn, Mg triangular diagrams. According to the figure, Fe$^{2+}$ occupies the cubic site (i.e. chloritoids are Fe-rich).

f) Staurolite
Staurolite analyses are listed in Table 3. The number of cations is calculated on the basis of 22 Oxygens. Staurolite in sample 49g, which is associated with chloritoid, has distinctly less MgO (~0.35%) and ZnO (~0.30%) than staurolite in sample 43c associated with andalusite and/or kyanite, with MgO (~1.22%) and ZnO (~1.78%). Staurolite do not show any significant zoning. Fig.6h, shows compositional ranges of staurolite on the Fe, Mg and (Mn+Zn) triangular diagrams. According to the figure, staurolites are Fe-staurolite and MnO and ZnO contents are very low. Staurolite shows lower X$_{Fe}$-value than coexisting garnet.

g) Feldspar
Feldspar analyses are listed in Table 3. The number of cations is calculated on the basis of 8 Oxygens. The anorthite content (XAn) of plagioclase is variable. For example in sample 44c XAn is 0.30 and in sample 13f it is 0.10. Figure 6i, illustrates the composition of feldspars on the Ca,
Na, K triangular diagram. According to the figure, plagioclases are albite-rich.

5- Discussion
5-1- Phase relation and reaction history of peak metamorphism (M2) in the chloritoid-free metapelitic rocks of the Bolandparchin sub-area

AFM compatibility diagrams, constructed based on real minerals chemistry, show phase relation for the garnet zone to sillimanite zone in the chloritoid-free metapelites (Fig.7).

a) The biotite-in isograd

The initial assemblage in the graphitic metapelitic rocks of the Bolandparchin sub area was probably, Kfs (detrial) + Chl + Ms + Qtz.

At the biotite-in isograd the first appearance of biotite in these rocks could be resulted from a KFMASH continuous reaction, such as

\[ \text{Kfs} + \text{Chl} = \text{Bt} + \text{Ms} + \text{Qtz} + \text{H}_2\text{O} \]  

The appearance of biotite in semi-pelitic rocks with detrital K-feldspar can be explained by this reaction.

Reaction (1) is also proposed by [10] for pelitic rocks from the Scottish Dalradian. We adopt the generally assumed temperature for the biotite in isograd of 370-400°C.

Bucher and Frey [14] discuss the equilibrium condition of such a reaction as a function of XFeO. The pelites lacking K-feldspar, dominate the metasedimentry sequence. In these rocks biotite forms most probably by the continuous reaction

\[ \text{Phe} + \text{Chl} = \text{Bt} + \text{Phe-poor Ms} + \text{Qtz} + \text{H}_2\text{O} \]  

According to Bucher and Frey [14] this reaction involves the progressive replacement of chlorite and the reduction of the phengite component in muscovite.

![Fig. 7.](https://example.com/f7.png)

The appearance of biotite in semi-pelitic rocks with detrital K-feldspar can be explained by this reaction.
b) The garnet-in isograd

The garnet-in isograd reaction is strongly depended on bulk-rock composition and MnO and CaO contents in the rocks. With high amount of these components, garnet could appear at temperatures below 450°C [15].

The appearance of garnet in the studied graphitic schists is most probably related to the two continuous reactions deduced from the AFM-phase compatibility diagrams (Fig.7 a to e).

\[
\text{Chl + Qtz = Grt + H}_2\text{O e.g.}[16] \quad (3)
\]

In Bolandparchin sub-area chloritoid does not occur, due to the MnO content of garnet, which produces an expansion of the Grt-Chl stability field to lower temperatures or to Al-poor bulk composition that contain Grt + Chl assemblages rather than chloritoid + biotite [17].

\[
\text{Chl + Ms = ky + Bt + H}_2\text{O} \quad (13)
\]

Reaction (12) generally occurs at low-pressure of the lower amphibolite facies, whereas reaction (13) occurs at medium-pressure of the lower amphibolite facies [5]. Two representative mineral assemblages formed during M2 metamorphic phase in the graphitic schists of the Bolandparchin sub-area are:

\[
\text{Bt + Ms + Grt + St + Ky + Qtz + Pl (medium-pressure type)} \\
\text{(a)}
\]

\[
\text{Bt + Ms + Grt + St + And + Qtz + Pl (low-pressure type)} \\
\text{(b)}
\]

\[
\text{St + Ms + Qtz = Al}_2\text{SiO}_5 + \text{Bt} + \text{H}_2\text{O} \quad (12)
\]

\[
\text{St + Bt + Qtz = Grt + Als + Ms + H}_2\text{O} \quad (10)
\]

\[
\text{St + Ms + Qtz = Sil + Grt + Bt + H}_2\text{O} \quad (11)
\]

Staurolite-Al2SiO5- in isograd

Staurolite is crystallized in both chloritoid-bearing and chloritoid-free rocks. Staurolite in the chloritoid-free, rocks could have been produced by the following discontinuous reaction.

\[
\text{Grt + MS + Chl = St + Bt + Qtz + H}_2\text{O} \quad [18] \quad (7)
\]

Garnet is partially resorbed by this reaction, and a significant amount of chlorite is removed, along with the production of abundant staurolite and new biotite.

According to [19], this reaction takes place at a fixed temperature for any given pressure, because it is discontinuous and proceeds until one of the three reactants has been consumed. When this reaction ceases, additional staurolite may be produced by a continuous reaction involving the remaining phase, for example

\[
\text{MS + Chl = St + Bt + Qtz + H}_2\text{O} \quad (8)
\]

This reaction may be deduced from AFM phase compatibilities and metamorphic textures, in that staurolites occurs mainly in phyllosilicates-rich layers [e.g.20]. These reactions account for the disappearance of primary chlorite in the staurolite-andalusite zone.

Staurolite does not appear in samples 13f and 44c (And +Grt + Bt + Ms) but exists as inclusions in andalusite, therefore, the following reaction can be considered for staurolite breakdown:

\[
\text{St + Ms + Qtz = Bt + And/Ky + H}_2\text{O} \quad (9)
\]

The low pressure andalusite-bearing rocks are mainly exposed in the Bolandparchin area. The appearance of andalusite is most probably related to the reactions

\[
\text{Chl + Ms = And + Bt + H}_2\text{O} \quad (12)
\]
deduced from the AFM-phase compatibilities (Fig.8a, b, c)
Ctd + Chl + Qtz = Grt + H₂O [22]               (5)
Fe-chloritoid + annite = almandine + muscovite + H₂O

b) The Staurolite-in isograd
In the chloritoid schists (non-graphitic rocks),
textural relations show the formation of staurolite
at the expense of garnet (Fig.5) suggesting the
following reaction
Ctd = St + Grt (Alm) + Chl + H₂O [23]             (11)
The appearance of staurolite in sample 49g is
the result of the continuous Fe–Mg–Mn reaction.
The garnet in the garnet zone samples occurs as an
extra phase, stabilized by Mn [e.g. 24] (Fig.8d, e, f,
g). In the AFM system, the garnet zone samples at
a given temperature (T₁) are characterized by co-
existing chlorite and chloritoid. At higher
metamorphic temperatures (T₂), the reaction:

chloritoid = garnet + staurolite + chlorite, results in
the demise of chloritoid in the higher grade rocks
and the appearance of staurolite and continued
garnet growth. These garnet-bearing rocks are
better illustrated in the AFMn system when
projected from chlorite. The stable garnet zone (T₁)
sub-assemblage is chloritoid+garnet+chlorite
(Sample 49g). As temperature increases to T₂, the
three phase assemblage chloritoid + garnet +
staurolite shifts to lower Mn until chloritoid is
consumed leaving the garnet+staurolite+chlorite
sub-assemblage (Sample 47b).

As it can be seen, the appearance of staurolite is
not the result of a garnet consuming reaction such
as garnet + chlorite = staurolite + biotite +H₂O, as
in low-Al pelites (because biotite is not formed in
the studied rocks). Therefore, we conclude that
garnet in these samples did not experience any
dissolution due to the appearance of staurolite.

**Fig. 8.** a,b,c, Al₂O₃-FeO-MgO projection from quartz, muscovite and H₂O of coexisting minerals in Non-graphitic
schists of the Poshtuk sub-area. d,e,f,g, AFMn plots showing the phase relation for the garnet zone and staurolite zone
samples.
6- Conclusion

The main mineral assemblage of peak metamorphism in the graphitic metapelites (chloritoid-free schist) of the BolandParchin is garnet, fibrolite, biotite, muscovite and quartz. Chloritoid-bearing metapelites of the Poshtuk sub-area contain the assemblage of garnet, staurolite, chlorite, muscovite, chloritoid and quartz; AFM compatibility diagrams, constructed based on real minerals chemistry, show the phase relations for the garnet zone to sillimanite zone in the chloritoid-free metapelites. The isograds are typical Barrovian type.

AFM and AFMn compatibility diagrams show the phase relations for the garnet zone and staurolite zone samples in the chloritoid-bearing metapelites. The deduced isograds based on the field geology studies and petrographical inspection of the samples are not typical Barrobian type, but reflect the first appearance of chloritoid minerals in these aluminous bulk compositions.

Since biotite is not crystallized in the studied samples, the appearance of staurolite can not be attributed to the garnet consuming reaction as happens in most of the low Al-pelites of the world. Therefore there are two distinct mechanisms for staurolite crystallization in the chloritoid-bearing and chloritoid-free rock studied here.

The stable garnet zone assemblage is chloritoid + garnet + chlorite. As temperature increases the three phase assemblage chloritoid + garnet + staurolite shifts to lower Mn contents until chloritoid is consumed leaving the garnet + staurolite + chlorite assemblage.

Acknowledgements

The main analytical part of the research was carried out in the Geosciences Institute of Potsdam University and GFZ, Potsdam, Germany. We would like to thank fruitful discussions with A. Muller and P. O’Brien from Potsdam University. Dr. Rhede and O. Appelt are acknowledged for their generous help during microprobe sessions. Constructive comments by two anonymous referees of the journal improved the manuscript. We thank editorial efforts by Dr. Tajabor and Dr. Homam.
